HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Thermal conductivity for a chain of anharmonic oscillators perturbed by a conservative noise

Cédric Bernardin

Abstract We consider d -dimensional chains of (an)harmonic oscillators we perturb by a noise conserving energy or energy and momentum. We review the thermal conduction properties we obtained for these systems ([8], [1], [6], [2]) and conclude by several open questions.

1 Introduction

The derivation of phenomenological laws from a microscopic description of the matter is one of the goals of statistical mechanics. Among them Fourier's law is probably one of the simple: when a small gradient ∇T of temperature is applied to a material, in the steady state, the energy flux J is proportional to the gradient of temperature

$$J = -\kappa \nabla T$$

The proportionality coefficient κ is called the thermal conductivity. Despite its simplicity and the interest it has in the physical and mathematical community the derivation of Fourier's law from a microscopic model remains one of the main open question of nonequilibrium statistical mechanics ([17], [11], [15]).

In insulating crystals heat is transported by lattice vibrations, and since the pioneering work of Debye, systems of coupled anharmonic oscillators have been used as microscopic models for heat conduction. They are classical system of particles interacting through a nearest neighbour interaction potential V and which are in an external potential W . The Hamiltonian \mathcal{H} is given by

$$\mathcal{H} = \sum_{x \in \Lambda} \left(\frac{|p_x|^2}{2m_x} + W(q_x) + \sum_{|y-x|=1} V(q_x - q_y) \right), \quad \Lambda \subset \mathbb{Z}^d$$

where m_x, q_x, p_x denotes the masse, position and momentum of the particle with equilibrium position $x \in \Lambda$.

It is well known that harmonic chains, because of their infinitely many conserved quantities, have infinite conductivity and do not obey Fourier's law ([19]). This because phonons can traverse ballistically along the chain. It is often expected that enough strong nonlinearity or disorder (like the presence of random masses) causes scattering between phonons and should imply a sufficiently fast decay of correlations for heat current and hence a normal conductivity. A rigorous treatment of a nonlinear system, even the proof of the existence of the conductivity coefficient, seems to be out of reach of current mathematical techniques. In this context the understanding of the coupled effect of nonlinearity and disorder is a challenge.

The situation is in fact more complex. In some low dimensional systems ($d \leq 2$) anomalous thermal conductivity is observed numerically and experimentally in nanotubes technology. The anomalous conductivity in low dimension has attracted a lot of attention in the literature, and it has been suggested that conservation of momentum is an important ingredient. There is no agreement, theoretically and numerically, about the exact dependance of the conductivity with the size of the system ([17]).

Hence it makes sense to look at simple models which incorporate the important features that one believes are necessary to see normal transport. The main difficulty in Hamiltonian dynamics with a large number of degrees of freedom is to show that they behave ergodically, e.g. that the only time invariant measures locally absolutely continuous w.r.t. Lebesgue measure are, for infinitely extended spatial uniform systems, of the Gibbs type. For some stochastic lattice gases it can be proven but it remains a challenging problem for Hamiltonian dynamics. Taking advantage of mathematical techniques developed in the hydrodynamic limits community we introduce hybrid models between purely Hamiltonian systems and purely stochastic models which remain mathematically tractable but are sufficiently close to realistic systems to reproduce at least qualitatively what is observed for these systems. We consider chains of oscillators perturbed by a stochastic noise conserving energy or energy and momentum. These stochastic perturbations are here to simulate (qualitatively) the effective (deterministic) ergodicity coming from the Hamiltonian dynamics.

The paper is organized as follows. In section 2 we introduce a model of coupled oscillators perturbed by a noise: the first noise conserves only energy and the second one conserves energy and momentum. In section 3 we review linear response theory and Green-Kubo formula. Section 4 is devoted to the study of a chain of oscillators with the noise conserving only energy. For the harmonic homogenous harmonic chain we show Fourier's law is valid and compute the conductivity. For anharmonic chains we provide lower and upper bounds. The effect of disorder is considered in subsection 4.3. Then we consider the energy-momentum conserving model in section 5 and show that in the homogenous harmonic case a breakdown of Fourier's law holds for low dimensional momentum conserving systems. We provide also

upper bounds for the conductivity in the anharmonic case. We conclude the paper by open question in section 6.

Notations : The canonical basis of \mathbb{R}^d is noted (e_1, e_2, \dots, e_d) and the coordinates of a vector $u \in \mathbb{R}^d$ are noted (u^1, \dots, u^d) . Its Euclidian norm $|u|$ is given by $|u| = \sqrt{(u^1)^2 + \dots + (u^d)^2}$ and the scalar product of u and v is $u \cdot v$.

If N is a positive integer, \mathbb{T}_N^d denotes the d -dimensional discrete torus of length N and we identify $x = x + kNe_j$ for any $j = 1, \dots, d$ and $k \in \mathbb{Z}$.

If F is a function from \mathbb{Z}^d (or \mathbb{T}_N^d) into \mathbb{R} then the (discrete) gradient of F in the direction e_j is defined by $(\nabla_{e_j} F)(x) = F(x + e_j) - F(x)$ and the Laplacian of F is given by $(\Delta F)(x) = \sum_{j=1}^d \{F(x + e_j) + F(x - e_j) - 2F(x)\}$.

2 The models

In this section we introduce deterministic nonlinear chains on a multidimensional lattice perturbed by a stochastic noise. The stochastic perturbations are such that they exchange momentum between particles with a local random mechanism that conserves total energy or total energy and total momentum.

2.1 Closed system

We first consider the closed system with periodic boundary conditions. The atoms are labeled by $x \in \mathbb{T}_N^d$. Momentum of atom x is $p_x \in \mathbb{R}^d$, its displacement from its equilibrium position is $q_x \in \mathbb{R}^d$ and its mass is $m_x > 0$. The configuration space is given by $\Omega_N = \{(q_x, p_x) \in \mathbb{R}^d \times \mathbb{R}^d; x \in \mathbb{T}_N^d\}$. The Hamiltonian is given by

$$\mathcal{H}_N = \sum_{x \in \mathbb{T}_N^d} \left[\frac{|p_x|^2}{2m_x} + W(q_x) + \frac{1}{2} \sum_{|y-x|=1} V(q_x - q_y) \right].$$

We assume that V and W have the following form:

$$V(q_x - q_y) = \sum_{j=1}^d V_j(q_x^j - q_y^j), \quad W(q_x) = \sum_{j=1}^d W_j(q_x^j).$$

and that V_j, W_j are smooth, non-negative and even. We call V the interaction potential, and W the pinning potential. The case where $W = 0$ will be called unpinned.

In the sequel we will refer to the (α, ν) -harmonic case:

$$V_j(r) = \alpha r^2, \quad W_j(q) = \nu q^2, \quad \alpha > 0, \quad \nu \geq 0 \quad (1)$$

for which explicit and generic results can be obtained.

The generator \mathcal{L}_N of the dynamics is defined by

$$\mathcal{L}_N = \mathcal{A}_N + \gamma \mathcal{S}_N$$

where \mathcal{A}_N is the Liouville operator corresponding to the Hamiltonian \mathcal{H}_N

$$\mathcal{A}_N = \sum_x \{ \partial_{p_x} \mathcal{H}_N \cdot \partial_{q_x} - \partial_{q_x} \mathcal{H}_N \cdot \partial_{p_x} \}$$

and \mathcal{S}_N is the generator of the Markovian noise. The parameter $\gamma > 0$ regulates the strength of the noise. It acts only on momenta and is local. It consists in an infinitesimal exchange of momenta preserving some conservation laws. The first conservation law we impose is the energy conservation. Since the noise acts only on momenta it is equivalent to require conservation of kinetic energy. This corresponds to the so-called *energy conserving noise*. If we require also the conservation of total momentum then we get a second noise we call the *energy-momentum conserving noise*. Let us denote $\pi_x = p_x / \sqrt{m_x}$. In the homogeneous case $m_x = 1$, $\pi_x = p_x$.

The two noises have the following form

$$\mathcal{S}_N = \frac{1}{4} \sum_{i,j=1}^d \sum_{\substack{x,z \in \mathbb{T}_N^d \\ |x-z|=1}} (X_{x,z}^{i,j})^2$$

where $X_{x,z}^{i,j}$ is equal to

$$X_{x,z}^{i,j} = \pi_z^j \partial_{\pi_x^i} - \pi_x^i \partial_{\pi_z^j}$$

for the energy conserving noise and equal to

$$X_{x,z}^{i,j} = (\pi_z^j - \pi_x^j)(\partial_{\pi_z^i} - \partial_{\pi_x^i}) - (\pi_z^i - \pi_x^i)(\partial_{\pi_z^j} - \partial_{\pi_x^j}).$$

for the energy-momentum noise if $d \geq 2$. If $d = 1$ in order to conserve total momentum and total kinetic energy, we have to consider a random exchange of momentum between three consecutive atoms ([2]).

The interpretation of the vector fields is the following. To be specific we take $d = 1$ and consider the energy conserving noise. In this case $X_x = X_{x,x+1}^{1,1} = (\pi_{x+1} \partial_{\pi_x} - \pi_x \partial_{\pi_{x+1}})$. Observe that X_x is the vector field tangent to the circle $C_x = \{(\pi_x, \pi_{x+1}); \pi_x^2 + \pi_{x+1}^2 = 1\}$ so that X_x^2 generates a diffusion on C_x . In fact it is nothing else than a standard Brownian motion on the circle. The generator \mathcal{S}_N corresponds to a system of coupled Brownian diffusions preserving the kinetic energy $\sum_{x \in \mathbb{T}_N^d} |\pi_x|^2$. The energy-momentum conserving noise is defined by a similar procedure but the surface C_x has to be replaced by the surface of constant kinetic energy and constant momentum. In dimension 1, this surface is reduced to a point and it explains why we have to consider a three-body interaction.

Because the noise conserves energy, a family of stationary translations invariant probability measures for \mathcal{L}_N is given by the Gibbs measures. In the energy

conserving case they are parametrized by inverse temperature $\beta = T^{-1}$ and in the energy-momentum conserving model by inverse temperature β and mean momentum average \bar{p} . We denote the Gibbs measure with inverse temperature $\beta = T^{-1}$ and zero momentum average by $\mu_{N,T}$. It is given by

$$\mu_{N,T}(d\mathbf{q}d\mathbf{p}) = Z_{N,T}^{-1} \exp(-\beta \mathcal{H}_N) d\mathbf{q}d\mathbf{p}$$

where $Z_{N,T}$ is the partition function. Expectation with respect to $\mu_{N,T}$ is denoted by $\langle \cdot \rangle_{N,T}$. Remark that in $\mathbb{L}^2(\mu_{N,T})$ the Hamiltonian vector field \mathcal{A}_N is antisymmetric and the noise \mathcal{S}_N is symmetric.

2.2 Open system

We now consider the case where the system is in contact with thermal baths at different temperatures T_ℓ and T_r . Thermal baths are given by Ornstein-Uhlenbeck processes with the corresponding temperature. To simplify notations we take $d = 1$. The configuration space is now given by $\chi_N = \{(p_x, q_x) \in \mathbb{R} \times \mathbb{R}; x = 1, \dots, N\}$. The generator of the evolution has the form

$$\begin{aligned} \mathcal{L}_N &= \sum_{x=1}^N \{ \partial_{p_x} \tilde{\mathcal{H}}_N \cdot \partial_{q_x} - \partial_{q_x} \tilde{\mathcal{H}}_N \cdot \partial_{p_x} \} \\ &\quad + \frac{\gamma}{2} \sum_{x=1}^{N-1} (X_{x,x+1}^{1,1})^2 + \frac{1}{2} (T_\ell \partial_{p_1}^2 - p_1 \partial_{p_1}) + \frac{1}{2} (T_r \partial_{p_N}^2 - p_N \partial_{p_N}) \end{aligned}$$

We have to specify boundary conditions for $\tilde{\mathcal{H}}_N$. For example one can define

$$\tilde{\mathcal{H}}_N = \sum_{x=1}^{N-1} \left[\frac{|p_x|^2}{2m_x} + W(q_x) + \frac{1}{2} \sum_{|y-x|=1} V(q_x - q_y) \right].$$

with q_0 and q_{N+1} fixed.

Even if one can prove there exists a unique stationary probability measure $\langle \cdot \rangle_{N,ss}$ for the process, there is in general no formula to express it. The only case where one knows $\langle \cdot \rangle_{N,ss}$ is the equilibrium case $T_\ell = T_r = T$ where the stationary measure is given by the Gibbs measure at temperature T . Otherwise the probability measure $\langle \cdot \rangle_{N,ss}$ is called a *nonequilibrium* stationary state.

3 Thermal conductivity and linear response theory

In this section we review briefly linear response theory and Green-Kubo formula for thermal conductivity. Derivation of the Green-Kubo formula is heuristic and even

its (mathematical) existence is a challenging problem. Roughly speaking Green-Kubo formula is the space-time variance of the total current at equilibrium. Thermal conductivity is a transport coefficient defined by considering the system out of equilibrium. Linear response theory express the fact that if temperatures T_ℓ and T_r are different but close then a linear approximation is valid and the thermal conductivity $\kappa(T)$ is equal to the Green-Kubo formula $\kappa^{GK}(T)$. Such a formula belongs to the family of *fluctuation-dissipation* theorems since it relates dissipation (i.e. the thermal conductivity) to fluctuations (i.e. fluctuations of the total current).

Defining the energy of the atom x as

$$\mathcal{E}_x = \frac{1}{2m_x} p_x^2 + W(q_x) + \frac{1}{2} \sum_{y:|y-x|=1} V(q_y - q_x)$$

the energy conservation law can be read locally as

$$\mathcal{E}_x(t) - \mathcal{E}_x(0) = \sum_{k=1}^d (J_{x-e_k,x}([0,t]) - J_{x,x+e_k}([0,t]))$$

where $J_{x,x+e_k}([0,t])$ is the total energy current between x and $x+e_k$ up to time t . This can be written as

$$J_{x,x+e_k}([0,t]) = \int_0^t j_{x,x+e_k}(s) ds + M_{x,x+e_k}(t)$$

In the above $M_{x,x+e_k}(t)$ are martingales that can be written explicitly as Itô stochastic integrals.

The instantaneous energy currents $j_{x,x+e_k}$ satisfy the equation

$$\mathcal{L}_N \mathcal{E}_x = \sum_{k=1}^d (j_{x-e_k,x} - j_{x,x+e_k})$$

and it can be written as

$$j_{x,x+e_k} = j_{x,x+e_k}^a + \gamma j_{x,x+e_k}^s \quad (2)$$

The first term in (2) is the Hamiltonian contribution to the energy current

$$\begin{aligned} j_{x,x+e_k}^a &= -\frac{1}{2} (\nabla V)(q_{x+e_k} - q_x) \cdot \left(\frac{\pi_{x+e_k}}{m_{x+e_k}^{1/2}} + \frac{\pi_x}{m_x^{1/2}} \right) \\ &= -\frac{1}{2} \sum_{j=1}^d V_j'(q_{x+e_k}^j - q_x^j) \left(\frac{\pi_{x+e_k}^j}{m_{x+e_k}^{1/2}} + \frac{\pi_x^j}{m_x^{1/2}} \right) \end{aligned}$$

while $j_{x,x+e_k}^s$ is the noise contribution.

For the energy conserving noise we have

$$j_{x,x+e_k}^s = -\frac{1}{d}\nabla_{e_k}|\pi_x|^2$$

In the energy-momentum conserving case, in $d \geq 2$, it is

$$j_{x,x+e_k}^s = -\nabla_{e_k}|\pi_x|^2$$

and in $d = 1$ is

$$j_{x,x+1}^s = -\nabla\varphi(\pi_{x-1}, \pi_x, \pi_{x+1})$$

$$\varphi(\pi_{x-1}, \pi_x, \pi_{x+1}) = \frac{1}{6}[\pi_{x+1}^2 + 4\pi_x^2 + \pi_{x-1}^2 + \pi_{x+1}\pi_{x-1} - 2\pi_{x+1}\pi_x - 2\pi_x\pi_{x-1}]$$

The particular form of j^s is not very important. What is relevant is the fact that $j_{x,x+e_k}^s$ is a *discrete gradient* $\nabla_{e_k}\phi_x$ of a local function ϕ_x . It means a weak form of Fourier's law is valid at the microscopic level as soon as we can relate ϕ_x to the (macroscopic) local temperature. Observe that it is not the case for the Hamiltonian part of the current and one of the main difficulties is to express j^a as the sum of a discrete gradient and a small term (see (10)).

3.1 Nonequilibrium setting

We consider the system out of equilibrium (see subsection 2.2) in contact with two heat baths at different temperatures T_ℓ and T_r in the first direction. The conductivity $\kappa(T)$ is defined by the thermodynamic limit

$$\kappa(T) = \lim_{T_\ell, T_r \rightarrow T} \lim_{N \rightarrow \infty} \frac{\langle j_{0,e_1} \rangle_{N,ss}}{T_\ell - T_r}$$

We have seen in the introduction one expects that for one and two dimensional systems conserving momentum such a limit is equal to infinity. In order to estimate this divergence one can study the finite size thermal conductivity

$$\kappa_N(T) = \lim_{T_\ell, T_r \rightarrow T} \frac{\langle j_{0,e_1} \rangle_{N,ss}}{T_\ell - T_r} \quad (3)$$

Under suitable conditions his quantity is well defined even for purely Hamiltonian chains but it is not straightforward. It is often expected that

$$\lim_{N \rightarrow \infty} \kappa_N(T) = \kappa(T)$$

but it is not obvious since there is an exchange of limits.

3.2 Green-Kubo formula

The difficulty arising in the study of $\kappa(T)$ is that we have no explicit representation of the nonequilibrium stationary state $\langle \cdot \rangle_{N,ss}$. Since T_ℓ and T_r are close it is suggestive to use a perturbative approach to compute $\kappa(T)$.

Performing a first order development in the stationary state $\langle \cdot \rangle_{N,ss}$ we get that

$$\kappa(T) = \kappa^{GK}(T)$$

where the Green-Kubo formula for the conductivity $\kappa^{GK}(T)$ is given by ([23], pp. 188–190)

$$\kappa^{GK}(T) = \lim_{t \rightarrow \infty} \lim_{N \rightarrow \infty} \frac{1}{2T^2 t} \sum_{x \in \mathbb{T}_N^d} \mathbb{E}_{N,T} [J_{x,x+e_1}([0,t]) J_{0,e_1}([0,t])] \quad (4)$$

Here $\mathbb{E}_{N,T}$ indicates the expectation with respect to the equilibrium dynamics starting with the Gibbs measure $\langle \cdot \rangle_{N,T}$ at temperature T . This definition itself is formal since we have to prove existence of the limits.

By standard stochastic calculus and a time-reversal argument ([2]) one can establish the following equality

$$\begin{aligned} & \frac{1}{2T^2 t} \sum_x \mathbb{E}_{N,T} (J_{x,x+e_1}([0,t]) J_{0,e_1}([0,t])) \\ &= (2T^2 N^d t)^{-1} \mathbb{E}_{N,T} \left(\left[\sum_x \int_0^t j_{x,x+e_1}^a(s) ds \right]^2 \right) + \frac{\gamma}{d} \end{aligned} \quad (5)$$

Here the term γ/d is due to the presence of the noise. This is the first term which is of interest. In view of the Green-Kubo formula the anomalous behavior of the conductivity should appear in a slow time-decay of the time correlation of the (Hamiltonian part) of the current.

Let us denote

$$\tilde{\mathfrak{J}}_{e_1} = \sum_{x \in \mathbb{T}_N^d} j_{x,x+e_1}^a$$

In order to study the large time behavior of

$$C(t) = \lim_{N \rightarrow \infty} C_N(t), \quad C_N(t) = (2T^2 t N^d)^{-1} \mathbb{E}_{N,T} \left(\left[\int_0^t \tilde{\mathfrak{J}}_{e_1}(s) ds \right]^2 \right)$$

we study the asymptotics as $N \rightarrow \infty$ and then $\lambda \rightarrow 0$ of the Laplace transform $\mathfrak{L}_N(\lambda)$ of $tC_N(t)$

$$\mathfrak{L}_N(\lambda) = \int_0^\infty e^{-\lambda t} t C_N(t) dt$$

By stationarity and integration by parts, we have

$$\mathfrak{L}_N(\lambda) = \frac{1}{\lambda^2 T^2} \int_0^\infty dt e^{-\lambda t} \mathbb{E}_{N,T} [\mathfrak{J}_{e_1}(t) \mathfrak{J}_{e_1}(0)]$$

Denote by $e^{t\mathcal{L}_N}$ the semigroup generated by \mathcal{L}_N and remark that $\mathfrak{J}_{e_1}(t) = e^{t\mathcal{L}_N} \mathfrak{J}_{e_1}$ then

$$\mathfrak{L}_N(\lambda) = \frac{1}{\lambda^2 T^2} \langle \mathfrak{J}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \mathfrak{J}_{e_1} \rangle_{N,T} \quad (6)$$

A normal finite conductivity corresponds (in a Tauberian sense) to a positive finite limit of $\lambda^2 \mathfrak{L}_N(\lambda)$ as $N \rightarrow \infty$ and then $\lambda \rightarrow 0$. In this case, the conductivity $\kappa(T)$ should be equal to the following form of the Green-Kubo formula

$$\kappa^{GK}(T) = \gamma/d + \lim_{\lambda \rightarrow 0} \lim_{N \rightarrow \infty} N^{-d} \langle \mathfrak{J}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \mathfrak{J}_{e_1} \rangle_{N,T} \quad (7)$$

No general argument gives the existence of the limits in (4) and in (7) nor that if they exist they are equal.

Observe that Green-Kubo formula (4) predicts only the value of the thermal conductivity $\kappa(T)$ (defined in the nonequilibrium setting). If the thermal conductivity is infinite it says a priori nothing about the behavior of the finite size thermal conductivity $\kappa_N(T)$ defined by (3). To overcome this problem we define the *truncated Green Kubo formula* by

$$\kappa_N^{GK}(T) = (2T^2 N^d t_N)^{-1} \mathbb{E}_{N,T} \left(\left[\sum_{\mathbf{x}} \int_0^{t_N} j_{\mathbf{x}, \mathbf{x} + \mathbf{e}_1}^a(s) ds \right]^2 \right) + \frac{\gamma}{d}$$

where $t_N = N/v_s$ with v_s the sound velocity defined by

$$v_s = \lim_{k \rightarrow 0} |\partial_{k^1} \omega(k)|$$

and where

$$\omega(k) = \left(\sum_{j=1}^d W_j''(0) + 4V_j''(0) \sin^2(\pi k^j) \right)^{1/2}$$

is the dispersion relation of the approximated linear system. This definition of the conductivity of the finite system is motivated by the following consideration: in the harmonic case the finite size thermal conductivity $\kappa_N(T)$ can be obtained by this truncation technique (in a rigorous way) and we expect this is still valid for the anharmonic chain. In the linear interactions approximation $\nabla_k \omega(k)$ is the group velocity of the k -mode waves, which are the heat carriers, and typically v_s is an upper bound for these velocities. Consequently t_N is the typical time a low k (acoustic) mode takes to cross around the system once (see[17]). Typically v_s is of order one and we will take $v_s = 1$ in the sequel.

4 Energy conserving model

In this section we state the results obtained for the energy conserving noise. As expected one can not obtain infinite conductivity for this model since momentum is not conserved. In the homogenous harmonic case one computes explicitly the Green-Kubo formula $\kappa^{GK}(T)$ and also the conductivity $\kappa(T)$ in the one-dimensional unpinned system. It turns out that $\kappa(T) = \kappa^{GK}(T)$ so that predictions of linear response theory is valid although the proof does not use perturbative arguments. In the anharmonic homogenous case one can establish lower and upper bounds for $\kappa^{GK}(T)$ indicating a positive finite conductivity. The proof of the convergence of the Green-Kubo formula in the anharmonic case remains open. We are also interested in the effect of disorder (random masses) in the energy conserving model. This is the content of subsection 4.3.

4.1 Homogenous harmonic chain

Here we consider the homogenous (α, ν) -harmonic case (1) with all masses equal to 1.

Let us define

$$D = \int_{\xi \in [0,1]^d} \left(\frac{4\alpha^2 \sum_{j=1}^d \sin^2(\pi \xi^j)}{\nu + 4\alpha \sum_{j=1}^d \sin^2(\pi \xi^j)} \right) d\xi^1 \dots d\xi^d$$

We have the following theorem

Theorem 1. $\kappa^{GK}(T)$ defined by (4) is finite (pinned or unpinned) in any dimension and given by

$$\kappa^{GK}(T) = \frac{D}{\gamma} + \frac{\gamma}{d}$$

Proof. Recall (6). A simple but crucial computation shows that

$$(\lambda - \mathcal{L}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} = \frac{\tilde{\mathfrak{J}}_{e_1}}{\lambda + \gamma}$$

Let $D_N = D_N(\alpha, \nu)$ be the constant

$$D_N = T^{-1} \alpha^2 \sum_{k=1}^d \langle (q_{e_1}^k - q_{-e_1}^k)^2 \rangle_{N,T} = \frac{1}{Nd} \sum_{\xi \in \mathbb{T}_N^d} \left(\frac{4\alpha^2 \sum_{j=1}^d \sin^2(\pi \xi^j / N)}{\nu + 4\alpha \sum_{j=1}^d \sin^2(\pi \xi^j / N)} \right)$$

One computes easily $\lim_{N \rightarrow \infty} \langle \tilde{\mathfrak{J}}_{e_1}, \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T}$ and after inversion of the Laplace transform, one gets

$$C_N(t) = \frac{D_N}{\gamma} \left(1 + \frac{1}{\gamma t} (1 - e^{-\gamma t}) \right)$$

Then theorem follows.

Observe that if the noise becomes weaker (i.e. $\gamma \rightarrow 0$), we obtain a purely homogeneous harmonic chain and the thermal conductivity is infinite.

In the following theorem we study the one-dimensional unpinned system in contact with two heat baths at temperature T_ℓ and T_r . We show that conductivity is finite and coincides with the Green-Kubo formula. The proof remains valid in any dimension and with or without pinning as soon as we are able to prove the following bound

$$\forall x \in \{1, \dots, N\}, \quad \langle e_x \rangle_{N,ss} \leq C \quad (8)$$

where $C > 0$ is independent of N . Unfortunately it has been proved only in the one dimensional unpinned case.

Theorem 2. [8] Consider the one dimensional (α, ν) -harmonic case (1) with $\nu = 0$. For any $\gamma > 0$

$$\lim_{N \rightarrow \infty} N \langle j_{x,x+1} \rangle = \alpha (\gamma + \gamma^{-1}) (T_\ell - T_r) \quad (9)$$

Hence we have $\kappa(T) = \kappa^{GK}(T) = \alpha(\gamma + \gamma^{-1})$

The proof of this theorem can be found in [8]. It is based on entropy production bounds and use an explicit decomposition of the current $j_{x,x+1}$ as the sum

$$j_{x,x+1} = \nabla \phi_x + \mathcal{L}_N h_x \quad (10)$$

where h_x, ϕ_x are two explicit local functions and ∇ is the discrete gradient. Hence the current is the sum of a dissipative part (a spatial gradient) and a fluctuating part (a time derivative). For this reason we call this equation a *microscopic fluctuation-dissipation relation* ([5],[7],[8]).

4.2 Homogenous anharmonic chain

The introduction of nonlinearity in the Hamiltonian dynamics complicates considerably the problem. We do not have any proof of the existence of $\kappa^{GK}(T)$ nor $\kappa(T)$. At least we have estimates which indicate that a finite strictly positive conductivity is expected. By strictly positive we mean that the Hamiltonian contribution to the Green Kubo formula (the second term in (7)) is strictly positive, the term γ/d being only due to the noise and of no interest for the study of conduction properties of the underlying deterministic dynamics. We consider the (formal) Green-Kubo formula (7).

Proposition 1. Assume that

$$N^{-d} \langle \mathfrak{J}_{e_1}, \mathfrak{J}_{e_1} \rangle_{N,T} \leq C$$

with a constant C independent of N . Then there exists a positive constant C' independent of N such that for any $\lambda > 0$ and N ,

$$N^{-d} \langle \tilde{\mathfrak{J}}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T} \leq C' \quad (11)$$

Observe that the assumption done in this proposition is natural and is satisfied for reasonable potentials V, W (see (12)). This shows that if Green-Kubo formula (7) converges then $\kappa^{GK}(T)$ is finite.

Proof. Introduce the following so-called $H_{1,\lambda}$ and $H_{-1,\lambda}$ norms defined by

$$\|f\|_{\pm 1,\lambda}^2 = \langle f, (\lambda - \gamma \mathcal{S}_N)^{\pm} f \rangle_{N,T}$$

We have the following variational formula ([6])

$$\langle \tilde{\mathfrak{J}}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T} = \sup_u \left\{ 2 \langle \tilde{\mathfrak{J}}_{e_1}, u \rangle_{N,T} - \|u\|_{1,\lambda}^2 - \|\mathcal{A}_N u\|_{-1,\lambda}^2 \right\}$$

To obtain the upper bound we forget the term $\|\mathcal{A}_N u\|_{-1,\lambda}^2$ and we get

$$\langle \tilde{\mathfrak{J}}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T} \leq \sup_u \left\{ 2 \langle \tilde{\mathfrak{J}}_{e_1}, u \rangle_{N,T} - \|u\|_{1,\lambda}^2 \right\}$$

It is well known that

$$\sup_u \left\{ 2 \langle \tilde{\mathfrak{J}}_{e_1}, u \rangle_{N,T} - \|u\|_{1,\lambda}^2 \right\} = \langle \tilde{\mathfrak{J}}_{e_1}, (\lambda - \gamma \mathcal{S}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T}$$

and a simple computation shows that

$$(\lambda - \gamma \mathcal{S}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} = \frac{\tilde{\mathfrak{J}}_{e_1}}{\lambda + \gamma}$$

We are left to prove that

$$N^{-d} \langle \tilde{\mathfrak{J}}_{e_1}, \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T} \leq C$$

with a constant C independent of N . It is exactly our assumption.

We expect also a lower bound of the form

$$C^{-1} \leq N^{-d} \langle \tilde{\mathfrak{J}}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T}$$

with $C > 0$ independent of λ and N .

The strategy to prove such a lower bound is straightforward: we have to find a good test function $v_{N,\lambda}$ and show that

$$N^{-1} \left\{ 2 \langle \tilde{\mathfrak{J}}_{e_1}, v_{N,\lambda} \rangle_{N,T} - \|v_{N,\lambda}\|_{1,\lambda}^2 - \|\mathcal{A}_N v_{N,\lambda}\|_{-1,\lambda}^2 \right\} \geq C^{-1}$$

Unfortunately we are not able to prove this lower bound for general V and W but only for unpinned systems ($W = 0$) in $d = 1$. We note $r_x = q_{x+1} - q_x$. Then the p 's and the r 's are independent variables under the Gibbs measure $\langle \cdot \rangle_{N,T}$. Some conditions on V are imposed

$$\text{Var}(V''(r_0)) \leq C, \quad \text{Var}(V'(r_0)) \leq C$$

with $C > 0$ and $\text{Var}(F(r_0))$ is the variance (independent of N) of $F(r_0)$ under the Gibbs measure $\langle \cdot \rangle_{N,T}$.

Proposition 2. *Under the conditions above there exists a positive constant C' independent of N and λ such that*

$$C' \leq N^{-1} \langle \mathfrak{J}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \mathfrak{J}_{e_1} \rangle_{N,T}$$

Proof. We choose

$$v_{N,\lambda} = -a \sum_x p_x (V'(r_x) + V'(r_{x-1})) = 2a \mathfrak{J}_{e_1}$$

with $a > 0$ we will precize later. We have

$$\mathcal{A}_N v_{N,\lambda} = -a \sum_x p_x^2 (V''(r_{x-1}) - V''(r_x))$$

Let $G_{\lambda,N}(z)$ the solution on \mathbb{T}_N of

$$(\lambda - \gamma \Delta) G_{N,\lambda} = \delta_0(\cdot)$$

Observe that $\mathcal{S}_N(p_x^2) = \Delta(p_x^2)$ then we get

$$(\lambda - \gamma \mathcal{S}_N)^{-1} (\mathcal{A}_N v_{N,\lambda}) = -a \sum_{x,z} G_{N,\lambda}(x-z) p_z^2 (V''(r_{x-1}) - V''(r_x))$$

It follows that

$$\|\mathcal{A}_N v_{N,\lambda}\|_{-1,\lambda}^2 = a^2 \sum_{x,y,z} G_{\lambda,N}(x-z) \langle p_y^2 p_z^2 (V''(r_{y-1}) - V''(r_y)) (V''(r_{x-1}) - V''(r_x)) \rangle_{N,T}$$

Observe now the Gibbs measure $\langle \cdot \rangle_{N,T}$ is product. Then an easy computation shows

$$\|\mathcal{A}_N v_{N,\lambda}\|_{-1,\lambda}^2 = Na^2 T \text{Var}(V''(r_0)) (\Delta G_{N,\lambda})(0)$$

By discrete Fourier transform we have

$$(\Delta G_{N,\lambda})(0) = \frac{1}{N} \sum_{k \in \mathbb{T}} \frac{4 \sin^2(\pi k/N)}{\lambda + 4\gamma \sin^2(k\pi/N)} \leq \gamma^{-1}$$

On the other hand we have

$$\begin{aligned} & 2 \langle \mathfrak{J}_{e_1}, v_{N,\lambda} \rangle_{N,T} - \|v_{N,\lambda}\|_{1,\lambda}^2 \\ &= 4a \langle \mathfrak{J}_{e_1}, \mathfrak{J}_{e_1} \rangle_{N,T} - 4a^2 \langle \mathfrak{J}_{e_1}, (\lambda - \gamma \mathcal{S}_N) \mathfrak{J}_{e_1} \rangle_{N,T} \\ &= 4a \langle \mathfrak{J}_{e_1}, \mathfrak{J}_{e_1} \rangle_{N,T} - 4a^2 (\lambda + \gamma) \langle \mathfrak{J}_{e_1}, \mathfrak{J}_{e_1} \rangle_{N,T} \end{aligned}$$

because $\mathcal{S}_N \tilde{\mathfrak{J}}_{e_1} = -\tilde{\mathfrak{J}}_{e_1}$. By a simple computation we have

$$\langle \tilde{\mathfrak{J}}_{e_1}, \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T} = 4NT \text{Var}(V'(r_0)) \quad (12)$$

If a is sufficiently small we get

$$N^{-d} \langle \tilde{\mathfrak{J}}_{e_1}, (\lambda - \mathcal{L}_N)^{-1} \tilde{\mathfrak{J}}_{e_1} \rangle_{N,T} \geq C^{-1}$$

with $C > 0$ independent of N and λ .

4.3 Disordered harmonic chain

In this subsection we are interested in the effect of disorder on the thermal conductivity properties. The simplest way to introduce randomness is to assume that masses of atoms can vary from site to site according to a random sequence. We first review basic facts for deterministic chains with random masses. As it is well known, the presence of disorder generally induces localization of the normal modes and one can expect to have a perfect thermal insulators ($\kappa_N(T) \rightarrow 0$). The only analytically tractable model is the one dimensional disordered harmonic chain (DHC). Surprisingly the behavior of the thermal conductivity depends on boundary conditions and on the properties of the thermostats ([12], [22]). This curious phenomenon has been studied in [14] (see also [21]) in a more general setting and it turns out that "the exponent [of κ_N] depends not only on the properties of the disordered chain itself, but also on the spectral properties of the heat baths. For special choices of baths one gets the "Fourier behavior"". If we add a pinning potential in the DHC, $\kappa_N(T)$ becomes exponentially small in N .

Recently, Dhar and Lebowitz ([16]) were interested in the effect of both disorder and anharmonicity. The conclusions of their numerical simulations are that the introduction of a small amount of phonon-phonon interactions in the DHC leads to a positive finite thermal conductivity.

We consider now the (α, ν) -harmonic chain with random masses and energy conserving noise. The noise should simulate in some sense nonlinearity effects and in view of the numerical simulations of [16] one would expect the model to become a normal conductor: $\kappa_N(T) \rightarrow \kappa(T)$ with $\kappa(T)$ finite and positive. We are not able to obtain interesting informations for $\kappa(T)$ but only for $\kappa^{GK}(T)$. Hence the behavior of the thermal conductivity is studied in the linear response theory framework by using the Green-Kubo formula. Behavior of the conductivity defined through Green-Kubo formula has not been studied for DHC. It would be interesting to know what is the order of divergence of the latter. For the perturbed DHC we obtain uniform finite positive lower and upper bounds for the d dimensional finite volume Green-Kubo formula of the thermal conductivity with or without pinning (Theorem 3) so that the thermal conductivity is always finite and positive. In particular it shows the presence of the noise is sufficient to destroy localization of eigen-functions in pinned DHC. Linear response approach avoids the difficulty to deal with a nonequilibrium setting

where effects of spectral properties of heat baths could add difficulties as in the case of purely DHC. In the nonequilibrium setting, we expect that since the Green-Kubo formula for the thermal conductivity of the perturbed DHC remains finite, it will not depend on the boundaries.

Theorem 3. [6] *There exists a positive constant $C > 0$ independent of λ and N such that*

$$\begin{aligned} C^{-1} &\leq \liminf_{\lambda \rightarrow 0} \liminf_{N \rightarrow \infty} \int_0^\infty e^{-\lambda t} N^{-d} \mathbb{E}_{N,T} [\tilde{\mathfrak{J}}_{e_1}(t), \tilde{\mathfrak{J}}_{e_1}(0)] dt \\ &\leq \limsup_{\lambda \rightarrow 0} \limsup_{N \rightarrow \infty} \int_0^\infty e^{-\lambda t} N^{-d} \mathbb{E}_{N,T} [\tilde{\mathfrak{J}}_{e_1}(t), \tilde{\mathfrak{J}}_{e_1}(0)] dt \leq C \end{aligned}$$

Proof. The proof is similar to what is presented in subsection 4.2 for the anharmonic case.

A priori the Green-Kubo formula $\kappa^{GK}(T)$ depends on the particular realization of the masses $\{m_x\}$. But a formal argument ([6]) suggests that if masses are distributed according to some stationary ergodic probability measure \mathbb{P}^* then $\kappa^{GK}(T)$ depends only on the statistics of the masses and not on the particular realization of the disorder. One can write formally an infinite Green-Kubo homogenized formula $\kappa_{hom.}(T)$ obtained by averaging over the masses. In order to define $\kappa_{hom.}(T)$ one has to consider the infinite volume dynamics with generator \mathcal{L} given by

$$\mathcal{L} = \sum_{x \in \mathbb{Z}^d} \{ \partial_{p_x} \mathcal{H} \cdot \partial_{q_x} - \partial_{q_x} \mathcal{H} \cdot \partial_{p_x} \} + \gamma \sum_{i,j,k=1}^d \sum_{x \in \mathbb{Z}^d} (X_{x,x+e_k}^{i,j})^2$$

and

$$\mathcal{H} = \sum_{x \in \mathbb{Z}^d} \frac{p_x^2}{m_x} + (\alpha \Delta - \nu) q_x \cdot q_x$$

Observe that the sums are taken over \mathbb{Z}^d . One can show that the dynamics with generator \mathcal{L} is well defined. Then we have

$$\kappa_{hom.}^{GK}(T) = \gamma/d + \lim_{\lambda \rightarrow 0} \mathbb{E}^* \left[\int_0^\infty dt e^{-\lambda t} \sum_{z \in \mathbb{Z}^d} \mathbb{E}_T [j_{0,e_1}^a(t) \tau_z j_{0,e_1}^a(0)] \right]$$

where τ_z denotes the shift on the configuration space and \mathbb{E}_T is the expectation corresponding to the infinite dynamics starting from the infinite volume Gibbs measure with temperature T .

Theorem 4. [6] *Assume that $\{m_x\}$ is stationary under \mathbb{P}^* and there are positive constants \underline{m} and \overline{m} such that*

$$\mathbb{P}^*(\underline{m} \leq m_x \leq \overline{m}) = 1$$

The Hamiltonian contribution to the homogenized Green-Kubo formula for the thermal conductivity $\kappa_{hom.}^{GK}(T) - \gamma/d$

$$\kappa_{hom.}^{1,1}(T) - \gamma/d = \lim_{\lambda \rightarrow 0} \mathbb{E}^* \left[\int_0^\infty dt e^{-\lambda t} \sum_{z \in \mathbb{Z}^d} \mathbb{E}_T [j_{0,e_1}^a(t) \tau_z j_{0,e_1}^a(0)] \right]$$

exists, is positive and finite.

Proof. The proof is based on functional analysis arguments ([4], [10], [6]).

5 Energy-momentum conserving model

We investigate the same problems as in the previous section but for the chain perturbed by the energy-momentum conserving noise. Momentum is then conserved by the total dynamics if it is conserved by the Hamiltonian dynamics which is the case if and only if the system is unpinned. Dramatic consequences in low dimensional systems appear. In fact we prove that for unpinned systems with harmonic interactions, thermal conductivity is infinite in 1 and 2 dimensions, while is finite for $d \geq 3$ or for pinned systems. So thermal conductivity in our model behaves qualitatively like in a deterministic nonlinear system, i.e. these stochastic interactions reproduce some of the features of the nonlinear deterministic hamiltonian interactions.

For anharmonic systems, even with the stochastic noise, we are not able to prove the existence of thermal conductivity (finite or infinite). If the dimension d is greater than 3 and the system is pinned, we get a uniform bound on the finite size system conductivity. For low dimensional pinned systems ($d = 1, 2$), we can show the conductivity is finite if the interaction potential is quadratic and the pinning is generic. For the unpinned system we have to assume that the interaction between nearest-neighbor particles is strictly convex and quadratically bounded at infinity. This because we need some informations on the spatial decay of correlations in the stationary equilibrium measure, that decay slowly in unpinned system. In this case, we prove the conductivity is finite in dimension $d \geq 3$ and we obtain upper bounds in the size N of the system of the form \sqrt{N} in $d = 1$ and $(\log N)^2$ in $d = 2$ (see Theorem 7).

5.1 Homogenous harmonic chain

Consider first the homogenous (α, ν) -harmonic case (1) with all masses equal to 1. In [1],[2], we obtained the following theorems.

Theorem 5. [2] *In the (α, ν) -harmonic case (1), the limit defining $\kappa^{GK}(T)$ exists. It is finite if $d \geq 3$ or if the on-site harmonic potential is present ($\nu > 0$), and is infinite in the other cases. When finite $\kappa^{GK}(T)$ is independent of T and the following formula holds*

$$\kappa = \frac{1}{8\pi^2 d \gamma} \int_{[0,1]^d} \frac{(\partial_{k^1} \omega)^2(k)}{\psi(k)} dk + \frac{\gamma}{d}$$

where $\omega(k)$ is the dispersion relation

$$\omega(k) = \left(v + 4\alpha \sum_{j=1}^d \sin^2(\pi k^j) \right)^{1/2}$$

and

$$\psi(k) = \begin{cases} 8 \sum_{j=1}^d \sin^2(\pi k^j), & \text{if } d \geq 2 \\ 4/3 \sin^2(\pi k)(1 + 2 \cos^2(\pi k)), & \text{if } d = 1 \end{cases}$$

Consequently in the unpinned harmonic cases in dimension $d = 1$ and 2 , the conductivity of our model diverges. We have the following behavior for the truncated Green-Kubo formula.

Theorem 6. [2] *In the harmonic case, if $W = 0$:*

1. $\kappa_N^{GK}(T) \sim N^{1/2}$ if $d = 1$,
2. $\kappa_N^{GK}(T) \sim \log N$ if $d = 2$.

In all other cases κ_N^{GK} is bounded in N and converges to $\kappa^{GK}(T)$.

The interest of these theorems is that they show energy-momentum conserving model reproduces the expected behavior of purely Hamiltonian nonlinear chains, meaning an infinite conductivity for low dimensional unpinned systems and a finite conductivity otherwise. Several microscopic stochastic models have been proposed in the past but none of them has this property with respect to momentum conservation and dimension.

The strategy of the proof is very similar to the proof given for the energy conserving model. Recall (7). Then the problem is reduced to solve the resolvent equation

$$\lambda u_{N,\lambda} - \mathcal{L}_N u_{N,\lambda} = \mathfrak{J}_{e_1}$$

Solving explicitly such an equation is in general very difficult. The key property of \mathcal{L}_N is that for quadratic potentials V and W it sends a polynomial function of p 's and q 's of degree k to a polynomial function of the same degree. Since \mathfrak{J}_{e_1} is of degree 2, $u_{N,\lambda}$ has to be searched in the smaller space of polynomial functions of degree 2. Moreover the translation invariance of \mathfrak{J}_{e_1} implies that $u_{N,\lambda}$ is in the form

$$u_{N,\lambda} = \sum_{x,y} f_{N,\lambda}(x-y) p_x \cdot p_y + \sum_{x,y} h_{N,\lambda}(x-y) q_x \cdot q_y + \sum_{x,y} g_{N,\lambda}(x-y) p_x \cdot q_y$$

where $f_{N,\lambda}, g_{N,\lambda}$ and $h_{N,\lambda}$ are functions from \mathbb{T}_N^d to \mathbb{R} . Then we obtain linear equations for $f_{N,\lambda}, g_{N,\lambda}$ and $h_{N,\lambda}$. It turns out that $f_{N,\lambda} = h_{N,\lambda} = 0$ and that $g_{N,\lambda}$ is simply related to the Green function of a symmetric simple random walk on \mathbb{T}_N^d . Then one computes easily

$$\langle u_{N,\lambda}, \mathfrak{J}_{e_1} \rangle_{N,T}$$

and we get the result.

5.2 Homogenous anharmonic chain

For the anharmonic chain we are not able to solve the resolvent equation

$$\lambda u_{N,\lambda} - \mathcal{L}_N u_{N,\lambda} = \mathfrak{J}_{e_1}$$

Nevertheless we can use the same strategy as the one explained in subsection 4.2. We introduce a variational formula to estimate by above

$$\langle u_{N,\lambda}, \mathfrak{J}_{e_1} \rangle_{N,T}$$

Extra assumptions on the potentials V and W assuring a uniform control on the canonical static correlations have to be done. We have this control as soon as V is strictly convex. In the pinned case $W > 0$, this control is “morally” valid as soon as the infinite volume Gibbs measure is unique. Exact assumptions are given in [9], theorem 3.1 and theorem 3.2. Hence ”general anharmonic case” will refer to potentials V and W such that this control is valid.

Theorem 7. [2] *Consider the general anharmonic case. There exists a constant C (depending on the temperature T) such that*

- For $d \geq 3$,
 1. either $W_j > 0$ is general
 2. or if $W_j = 0$ and $0 < c_- \leq V_j'' \leq C_+ < \infty$ for any j ,

then

$$\kappa_N^{GK}(T) \leq C.$$

- For $d = 2$, if $W_j = 0$ and $0 < c_- \leq V_j'' \leq C_+ < \infty$ for any j , then

$$\kappa_N^{GK}(T) \leq C(\log N)^2.$$

- For $d = 1$, if $W_j = 0$ and $0 < c_- \leq V_j'' \leq C_+ < \infty$, then

$$\kappa_N^{GK}(T) \leq C\sqrt{N}.$$

- Moreover, in any dimension, if V_j are quadratic and $W_j > 0$ is general then $\kappa_N^{GK}(T) \leq C$.

6 Open questions

In this section we mention several open questions. From the (probably) easier to the most difficult we have:

- Prove (8) in the d -dimensional linear pinned or unpinned case. It should be also valid in the nonlinear case.
- Consider the energy-momentum conserving model with linear interactions. We have studied the thermal conductivity in the Green-Kubo framework. Consider the same system but in contact with thermal baths at different temperatures. Can you say something about $\kappa_N(T)$? We expect it diverges like \sqrt{N} (resp. $\log N$) for $d = 1$ (resp. $d = 2$) in the unpinned case and converges in the other cases to a finite positive constant. In fact a similar unpinned one-dimensional model has been considered in [13],[18] and numerical and analytical (but not rigorous) results confirm this conjecture.
- Consider the (α, ν) -harmonic case with random masses and energy conserving noise. Can you say something about the temperature dependance of κ_{hom}^{GK} ? Can you prove the almost sure convergence (w.r.t. disorder) of the Green-Kubo formula to the homogenized Green-Kubo formula κ_{hom}^{GK} ?
- Consider the (α, ν) -harmonic case with random masses and energy-momentum conserving noise. We have still upper bounds for the truncated Green-Kubo formula similar to the one obtained for the homogenous nonlinear chain in theorem 7. Can you obtain lower bounds? In particular do you have a positive conductivity for pinned chains ?
- Can you prove convergence of the Green-Kubo formula for nonlinear chains with energy conserving noise ?
- Consider an homogenous nonlinear chain with energy-momentum conserving noise. Can you obtain (non trivial) lower bounds for the truncated Green-Kubo formula ? Can you prove convergence of the Green-Kubo formula in dimension $d \geq 3$ or for pinned systems ? Interesting and surprising numerical simulations are provided in [3].
- Consider an homogenous nonlinear chains with energy-momentum conserving noise in contact with two thermal baths at different temperatures. Can you say something about $\kappa_N(T)$?
- Consider a nonlinear chain with energy-momentum conserving noise and random masses. Can you say anything about $\kappa(T)$ or $\kappa^{GK}(T)$?
